Abstract

Two cases of cold air outbreak in November 2001 are analyzed on the basis of ozone concentration measurements and weather data at the mountain station (43°44' N, 42°43' E, 2070 m a.s.l.) near Kislovodsk, North Caucasus, Russia. Two cold fronts, with fast clearing up in the rear of the cloud zone, passed the station in the morning of 12 and 16 November. In both cases, the ozone concentration drops down to 7–8 ppb within the frontal cloud zones, under 100% relative humidity, *RH*, and then sharply increases to 43–45 ppb in dry (*RH* about 50%), cold air during several hours. After a warm front passage (12 November) or *RH* growth in the cold post-frontal air-mass (16 November), the ozone concentration decreases again to its average values near 30 ppb. Neither diurnal cycle nor photochemical generation could produce in the ozonometric data this specific “drop-and-peak” signature which is considered to be caused by cold outbreak with post-frontal flow of “dry air stream” type.

Synoptic situation and tropopause topography are analyzed using the objective analysis data and METEOSAT images in the water vapor radiation band. It is concluded that the ozone growth in the rear of the cold fronts is associated with sinking of substratospheric or stratospherically influenced air from the areas of tropopause folding. Motion of cold surges with their frontal zones, jet streams, and tropopause folds is analyzed, including development of wave disturbances at the streamers and formation of substratospheric air “tongues” underflowing the high tropopause and representing “aged” intrusions.

1. Introduction

The cold air outbreaks in deep tropospheric troughs and cut-off lows are associated with typical patterns of atmospheric fronts, jet streams and vertical motions. In the frontogenetic baroclinic zones, at the cold sides of jet streams, deep descending motions develop demonstrating themselves in the tropopause folding (e.g. Carlson, 1990;

Holton et al., 1995). As the upper-tropospheric and stratospheric air is very dry, the low tropopause areas, with their fine structure, are usually well-defined at the satellite images in the water vapor radiation band, WV (Appenzeller, 1996a, b). In the rear of the cold fronts, the conditions are, in principle, the most favorable for stratospheric air penetration to tropospheric levels and down to the surface. In the cold airmass behind the fronts, one can expect to find typical stratospheric air components, such as ozone and certain radioactive isotopes, especially the cosmogenic tracer of Be-7. In fact, a number of cases of increased Be-7 and ozone in the surface air have been described (e.g. Davies and Schuepbach, 1994; Moody et al., 1995; Chakina and Kuznetsova, 1997; Cooper et al., 1998).

Unlike Be-7, ozone can be generated by anthropogenic sources which can enhance post-frontal increase in cases of advection from industrially developed areas (Dickerson, 1995). According to the recent study by Cooper et al. (2002), in the midlatitude cyclones, the descending stratospheric (substratospheric) air is represented by “dry air stream” (in agreement with the conceptual model developed by Browning, 1974; Carlson, 1980; Browning and Roberts, 1994). The dry air stream, on average, descends to the levels about 600 mb and always advects stratospheric ozone into the middle and upper troposphere. Other estimates of the stratospheric air penetration depth can be found in Eisele et al. (1999), where it is shown from lidar data that ozone-rich descending air structures in most cases reached 3000 m a.s.l. On the other hand, Reiter (1991) concluded that the stratospheric intrusions do not penetrate lower than 1600 m a.s.l. Anyway, their detections at the lower levels are evidently rather rare events.

The dry air stream, which causes the sky clearing immediately after the cold front passage, must be distinguished from the properly post-frontal airstream which can be advected in the lower troposphere from industrial areas and thus can contain anthropogenic pollutants (Cooper et al., 2002).

It can be expected that the effects of dry airstreams connected with the cold fronts are more significant at higher elevations, that is, at the mountain stations. Indeed, as it has been shown in Schuepbach et al. (1999b), in the Alps, at the station of Jungfrau-

joch (3580 m a.s.l.), ozone increase (“spikes”) connected with a tropopause fold is pronounced much more than at another station (209 m a.s.l.) at the leeside of the mountain crest (90 and 65 ppb, respectively). At both stations no cloud or precipitation have been reported at the cold front preceding the ozone increase. Also, no impact of planetary boundary layer advection has been revealed, in contrast with Schuepbach et al. (1999a), where it is shown that even at Jungfraujoch elevation, the boundary layer advection of Mediterranean air contributes significantly to the observed ozone levels.

In their comprehensive study of stratospheric intrusion effects at Alpine stations, Stohl et al. (2000) have shown that vigorous stratospheric intrusions can cause ozone peaks to 70–90 ppb in the whole Alpine area along with the northern Apennines. Large extension of the stratospheric air volume at the middle-tropospheric and low-tropospheric levels (as revealed by measurements at the stations at 2165 to 3580 m a.s.l. and in some valleys) is found to be a result of accumulation of three different stratospheric intrusions. At the three Alpine stations the intrusions manifested themselves also in low relative humidity (RH) and high Be-7 concentrations. Before and after the intrusions (that is, in the frontal zones), high RH (100%) was observed along with low (30–40 ppb) ozone. Stohl et al. (2000) use RH in their observational climatology of stratospheric intrusions. However, they note that low RH may be associated with air descended from the upper troposphere undergoing adiabatic warming and thus may be used to identify “stratospherically influenced” air, but it is not a stratospheric tracer. Stohl et al. (2000) came to a conclusion that, in the Alpine region, stratospheric intrusions are significant for the ozone budget: in the boundary layer, their impact is limited, while in the lower free atmosphere, it is of great importance. Much of the stratospheric ozone arrives at the stations strongly diluted with tropospheric air.

Taking into account these results, one can expect that sharp cold fronts associated with cold air outbreaks may have a typical signature in the meteorological and ozonometric data: high RH and low ozone ahead and at the front, low RH and increased ozone (not necessarily to stratospheric values) in the rear of the front, in the descending air. This signature can be expected more pronounced at the mountain stations.

Cold air outbreaks and their signature in the ozonometric data

In the paper, two cases of cold air outbreak in November 2001 are analyzed using ozone measurements and weather data in the North Caucasus, Russia, at the Kislovodsk Scientific Mountain Station of the Oboukhov Institute for Atmospheric Physics, Russian Academy of Sciences.

2. Data and diagnostics

The station (43°44' N, 42°43' E, 2070 m a.s.l.) is located 18 km to the south of the town of Kislovodsk, on a plateau at the northern foothills of the Main Caucasian Ridge (which is about 48 km distant), in the vicinity of the Caucasian National Park. The region represents a health resort of the Caucasian Mineral Waters; industrial activity is minor and population low. The surface has a general slope to northeast. To the west, foothills of comparable altitude lie at distances of 50 km and more. (For more information about the station and its instrumentation see Senik et al., 2001).

Hourly data on ozone concentration, 3-h measurements of temperature, *RH*, clouds, visibility, and wind are analyzed. Large-scale atmospheric conditions are diagnosed from 00:00 and 12:00 UTC objective analysis data in the 2.5×2.5° gridpoints at 16 levels.

From the temperature, wind, and height objective analyses, Ertel potential vorticity, PV, is estimated. Potential temperature and PV vertical profiles are approximated with cubic spline-functions. Still, due to low space resolution of the data and scarcity of the radiosonde network (the only radiosounding station in the North Caucasus is Mineralnye Vody – the Russian for “Mineral Waters”), the resulting PV field can be expected smoothed. The PV field is used to derive the height of dynamic tropopause as a surface of constant PV threshold value. In the previously published works, the PV threshold value varies largely. So, it has been found that the surfaces of 4 pvu (Wirth and Egger, 1999) and 3.5 pvu (Hoinka, 1998; Chakina and Borisova, 1989, 1992) correspond closely to the conventional “thermal” tropopause (WMO, 1957) in the midlatitudes. Lower threshold values have been derived from radioactivity and ozone mea-

surements: Danielsen (1968) and Shapiro (1978) identified the dynamic tropopause as $PV=1$ pvu, while Stohl et al. (2000) suggest $PV=1.6$ pvu. It has been also shown that “ozonopause” or “ozone tropopause” is, on average, about 1000 m lower than the thermal tropopause (Bethan et al., 1996); this fact has been also reflected in (WMO, 1986) where ozonopause was admitted to be close to $PV=1.5$ pvu surface. To some extent, the PV threshold values depend on space resolution of wind and temperature data under use. In general, it seems to be convenient to consider PV values greater than 2 pvu to be stratospheric (Hoskins, 1991; Holton et al., 1995) and those between 1 and 2 pvu to be intermediate (substratospheric), while PV between 0.8 and 1 pvu can be interpreted as “stratospherically influenced”. The surface of 1 pvu thus will represent a “lower dynamic tropopause”.

The tropospheric jet stream positions and velocities are derived from the field of maximum winds computed using spline-approximated profiles of wind components at the gridpoints.

The frontal parameter, F , is diagnostically estimated in the gridpoints. The frontal parameter has been introduced in (Chakina et al., 2000, 2001) for the purpose of objective detection of frontal zones and represents a measure of pressure field curvature and baroclinicity in the lower half of the troposphere. Results and findings of (Huber-Pock and Kress, 1989) have been taken into account by Chakina et al. (2000, 2001).

The frontal parameter is computed in two steps:

1. The surface pressure field topography is objectively classified into the following 23 classes: center and 8 sectors (corresponding to 8 points of compass) of the low; trough; center and 8 sectors of the high; ridge; saddle; rectilinear isobars; low-gradient field. The classification is carried out through estimation of correlation rate between the pressure data in the area of 4×4 gridpoints (with the considered gridsquare in the center) and each of “standard fields” representing the classes. Among the obtained correlation rates >0.7 , a maximum is selected, and the pressure field in the central gridsquare is attributed to the corresponding class.

2. Calculation of F (dimensionless) as a linear function of two “predictors” which are different for different classes. The main predictors are:

$$\begin{aligned} & \left| \nabla ZTE_{850}^{500} \right|, \quad \left| \nabla ZTE_{925}^{700} \right|, \quad \left| \nabla T_{\text{surface}} \right|, \\ & \left| \nabla \left| \nabla ZTE_{850}^{500} \right| \right|, \quad \left| \nabla \left| \nabla ZTE_{925}^{700} \right| \right|, \quad \left| \nabla T_{e850} \right|, \\ 5 \quad & \left| \nabla T_{850} \right|, \quad \left| \nabla T_{925} \right|, \quad \left| \mathbf{V}_{850} \cdot \nabla T_{850} \right|, \\ & \nabla^2 H'_{925}, \quad \nabla^2 H'_{850} \end{aligned} \quad (1)$$

In total, 12 predictors are involved as describing temperature, humidity, height, and wind fields in the lower half of the troposphere.

In Eq. (1), ZTE is equivalent thickness (Huber-Pock and Kress, 1989):

$$10 \quad ZTE = - \sum_{P_l}^{P_u} \frac{R}{g} \bar{T}_e \ln \frac{P_u}{P_l} \quad (2)$$

– a quantity depending on equivalent temperature, T_e , distribution in the layer from P_l to P_u : $P_u = 500$ or 700 mb, $P_l = 850$ or 925 mb,

$$T_e = T + Lq/c_p, \quad (3)$$

$$\bar{T}_e = (T_{e,u} - T_{e,l}) / (\ln T_{e,u} - \ln T_{e,l}), \quad (4)$$

15 q is specific humidity, \mathbf{V} – wind velocity, L – evaporation heat, c_p – air specific heat under constant pressure.

The frontal parameter thus defined is found to be a good indicator of the frontal zones: the F contours produce two-dimensional picture of the surface frontal zones of finite width and quantitatively estimated sharpness (intensity). The areas with $F < 20$ are considered to be occupied by homogeneous airmasses or by those with low baroclinicity; $F \geq 20$ – zones of atmospheric fronts, $F \geq 60$ – zones of sharp atmospheric fronts.

Finally, the WV images from METEOSAT are also included into consideration.

3. Surface observations

In November 2001, two periods are observed (from 00:00 UTC 12 November to 09:00 UTC 13 November and from 03:00 UTC 16 November 02:00 UTC 17 November) with rather similar changes in ozone concentration (Fig. 1): a sharp drop (from 35 and 25–30 ppb on 12 and 16 November, respectively, to 7–8 ppb) and then a sharp growth (to 45 and 43 ppb, respectively). The ozone levels above 40 ppb are observed during 12 and 6 h on 12 and 16 November, respectively. Note that in both cases the ozone maxima are registered in the nighttime or in the early morning (local time is 3 h ahead UTC). Also, note that no diurnal cycle of ozone concentration is observed during the whole period shown in Fig. 1.

The increased ozone periods correspond closely enough to those of low RH (48–56 and <50% on 12 and 16 November, respectively), and ozone drops – to high RH (100%). However, on 12 November, the ozone drop starts at 00:00 UTC, while $RH=100\%$ is registered already at 12:00 UTC on 11 November, along with fog and 200–500 m visibility (no data are available on precipitation or fog/cloud microphysics). The whole day of 11 November air temperature is positive; in the night and morning, it drops to -4.2°C at 06:00 UTC (that is, at 09:00 LT) of 12 November and keeps negative till the end of the period of increased ozone. Evidently, a cold front passes in the night of 11 to 12 November and a warm one – in the morning of 13 November: temperature remains positive, after 06:00 UTC on 13 November, during next three days, with a maximum of 10.1°C on 14 November. All this time, a homogeneous airmass (with westerly winds to 6 m/s, not shown) occupies the area. The airmass is dry enough ($RH<70\%$ almost during the whole days of 13 and 14 November); not before the evening of 16 November, RH grows to 90%. On 15 November, cold advection appears: temperature decreases, convective clouds develop (in the daytime, Cu and Cb clouds are registered several times). In the morning of 16 November, another cold front passes, with Cb clouds and $RH=100\%$. Then, the sky clears up, and the dry airmass comes with a new peak of ozone.

Interactive Discussion

In both cases, typical changes in ozone concentration (“drop-and-peak”) are associated with cold fronts. The ozone drops are observed just in the zone of frontal clouds and $RH=100\%$, the peaks correspond to clear sky and dry, cold air (in the nighttime!). On 12 November, the increased ozone period ends with the warm front passage; on 16 November, the end of increased ozone is associated with RH increase and convective activity development, evidently caused by secondary fronts in the post-frontal airmass. Indeed, the cold advection continues, and air temperature keeps decreasing (down to -16.2°C at 06:00 UTC 18 November).

So, the surface observations show that

- both cold fronts exhibit the same signature in the ozonometric (and RH) data;
- the warm front has no such signature;
- ozone concentration increases directly after cold front passage, in the dry and cold airmass; when cold, but moist air, or dry, but warm one comes, – ozone concentration decreases to its background value.

4. Tropopause topography

To describe the tropopause topography, the $PV=1$ pvu surface – lower dynamic tropopause – is used along with WV satellite images. In the gridpoints with vertical PV profiles containing more than one level with $PV=1$ pvu, the upper of these levels is taken to construct the tropopause charts. The volumes with $PV \geq 1$ pvu found at lower levels are shown in the cross-sections of PV and equivalent potential temperature, θ_e (see Sect. 7).

In Figs. 2, 3, pressure at 1 pvu surface at 00:00 and 12:00 UTC is displayed along with WV images available at the nearest time. In Figs. 2a and c, a characteristic pattern of waves (or vortices) can be seen on the dry air band, oriented from north-east to

Interactive Discussion

south-west, as a clear manifestation of hydrodynamic instability. According to the satellite data between the objective analysis times (not shown), the waves developed about 14:30 UTC on 11 November. In the rear sector of one of the waves, maximum sinking (the darkest area in the WV image, Fig. 2a at 00:00 UTC 12 November is observed to the west of the station. Respectively, the leading sector of the wave – and, probably, originating lifting - is associated with a lighter area to the east. In Fig. 2b maxima of pressure at 1 pvu – that is, tropopause funnels – correspond to the sinking areas of two vortices in Fig. 2a. At 12:00 UTC (Figs. 2c and d), the station position is near the west edge of the dark area at WV image and of the tropopause funnel.

At 02:30 UTC of 12 November (Fig. 2a), two secondary dark bands are seen at the WV image, in the rear of the primary one. A narrow band, also with wavelike disturbances, is oriented approximately along 50° N to the west of Kiev, then it turns to the north-east and lies to the north of Volgograd and to the south of Nizhny-Novgorod. This band, apparently having no counterpart in the PV field, will be considered as intermediate between the primary streamer and the arch-shaped dry band oriented from Stockholm to Riga, Moscow, and Syktyvkar and corresponding to the deep streamer in Fig. 2b.

On 16 November (Fig. 3), the stratospheric streamer is deep and well-defined at 00:00 UTC and 02:30 UTC. Hydrodynamic instability in this case also develops, though not so pronounced; longer (as compared with Fig. 2) waves can be seen along the streamer. About 12:00 UTC (Figs. 3c and d) the streamer, to a large extent eroded by wave instability, has evidently passed the station. Unlike on 12 November, only the leading sector of the wave (and not its rear sector) – and thus an area of weaker sinking or even originating lifting in certain layer – passes over the station.

At 02:30 UTC of 16 November (Fig. 3a), a very distinct arch of dry air is observed at a slightly southern position than the analogous feature in Fig. 2a – from the Gulf of Bothnia to Riga, Minsk, and Moscow. At 12:00–12:30 UTC (Figs. 2c and d), this arch-shaped tropopause fold approaches the coasts of the Black and Azov Seas. Again, note a general good agreement between the WV and PV-derived locations of the

Interactive Discussion

tropopause folds.

So, in both cases – on 12 and 16 November – the tropopause folds, subject to wave instability, passed over the station between 00:00 and 12:00 UTC, that is, immediately after the cold front passages as determined from Fig. 1. However, as it can be seen both from WV and PV pictures, the fold passages and the ozone peaks are not synchronous. Indeed, the ozone maxima are reached at 23:00 and 19:00 UTC on 12 and 16 November, respectively, while at 17:30 and 12:30 UTC, respectively, the station lies in the rear of the tropopause folds.

5. Surface fronts

The surface frontal zones (computed within 30 to 70° N latitude band) and the 700 mb height and temperature are shown in Fig. 4. The frontal zones outlined by $F=20$ contours are well-defined ($F > 100$ in the maxima). The cold air outbreaks on 12 and 16 November have clear similar features: rather narrow tongues of cold air are oriented to the east Black Sea (12 November, Fig. 4b) and to the Azov Sea and central Black Sea (16 November, Fig. 4d), in the rear of the tropopause folds. In the deep low with a center over the Cola Peninsula on 12 November and to the south of the White Sea on 16 November, occlusions and cold fronts correspond to the rear, arch-shaped tropopause folds. Two cold air surges are observed in both cases, associated with two frontal systems and two tropopause folds. Apparently, the intermediate dry air band from Fig. 2a (sketched in Fig. 4b) does not correspond to any separate frontal zone at the surface.

6. Jet streams

The tropospheric jet streams are parallel to the surface fronts and the tropopause folds (Fig. 5). Yet, they are shifted to the rear of the cold fronts, while the tropopause folds

Interactive Discussion

are shifted, with respect to the jet stream axes, to the cold airmass. Thus, sinking motions are associated with cold sides of the jet streams. Over the area under study, on 12 November, maximum winds do not reach 30 m/s – a threshold value for the tropospheric jet stream; on 16 November, the maximum winds here but slightly exceed 30 m/s. The strong jet streams (>50 and >80 m/s on 12 and 16 November, respectively) are associated with the second cold surges and the arch-shaped tropopause folds.

7. Vertical cross-sections

For 12:00 UTC 12 November, zonal and meridional cross-sections of PV and θ_e fields are shown in Fig. 6. The surface topography profiles are taken from the Terrain Base CD-ROM Version 1.1 (1995), National Geophysical Data Center, Boulder, CO, USA, with 10-minute resolution. The profiles shown in the cross-sections represent well topography of the area, though position of the station at the terrain is given roughly.

The isentropes outline a cold airmass of limited dimension over the Caucasus, along the latitude circle (Fig. 6a). In the meridional cross-section (Fig. 6b), the baroclinic zone appears near 40–45° N as connected with the cold surge and corresponds to the cold front which, at this time, already has passed the station. In the middle troposphere, warm advection zone comes to the station (Fig. 6a): the winds are mainly westerly this time in the troposphere over the region. Another zone of steeply sloped isentropes exists in the upper half of the troposphere near 55° N (not shown), corresponding to the second cold surge. In agreement with θ_e field, a tropopause fold over the station is displayed in Figs. 6a and b; another fold associated with the second cold surge is partly shown in Fig. 6b at 52.5–55°N. The tropopause fold over the station is funnel-shaped, its lower part being sloped to the northwest with respect to the upper one. Due to this “lag” of the lower part of the funnel, its air could influence the ozonometric data during several hours after 12:00 UTC. The lower dynamic tropopause descends below 2500 m a.s.l..

The situation of 12 November is rather simple: a local 1 pvu-tropopause funnel, con-

Interactive Discussion

taining stratospheric air, passed over the station immediately after the cold front cloud band, that is, about 12:00 UTC. The funnel evidently does not reach the level of the station: the computed height of $PV=1$ pvu is several hundred meters above. However, taking into account possible smoothing of the funnel due to low resolution (and scarce radiosonde network in the area), we may conclude that stratospherically influenced air did reach the station and left its signature in the ozonometric and hygrometric data, before being replaced by warmer tropospheric air.

The case of 16 November is more complicated, though many features of similarity exist. In Fig. 7a, the station is in the cold airmass, to the west of the baroclinic zone. No continuous tongue of stratospheric air can be seen in the zonal cross-section. At the meridional cross-section (Fig. 7b), two baroclinic zones corresponding to two cold surges are displayed, as well as two tropopause folds.

The main difference is connected with the stratospheric tongue shape. So, on 12 November, the tongue of air with $PV \geq 1$ pvu is well-defined and evidently connected with the tropopause fold which, according to Fig. 2, is situated this time over the station. On 16 November, the tongue is less pronounced (at least in the zonal cross-section, Fig. 7a). From the meridional cross-section (Fig. 7b), one can conclude that the stratospherically influenced air, which could cause increased ozone, is connected not with the first cold surge, but with the second one. The lower part of the tongue of air with $PV \geq 1$ pvu in Fig. 7b is stretched to the west with respect to the tropopause fold (as viewed from above) for about 250 km and represents a quasi-horizontal layer in the middle troposphere, underlying and overlying the tropospheric air. Indeed, this air with $PV \approx 1$ pvu could affect the ozone measurements in the afternoon of 16 November and the next night.

Figure 8 helps one to reveal the three-dimensional view of PV field. Low vertical resolution of the data does not allow us to retrieve vertical structure in detail. Yet, some interesting features can be noted. The areas of increased PV at each level are stretched from south-west to north-east. It seems that the areas of high PV at 300 and 400 mb, in the north-west parts of the plots, correspond to deep tropopause fold

Interactive Discussion

(Fig. 3) near 50–52° N and 40–45° E, which appears also at 500 mb surface in Fig. 8 as contoured by PV=1 and 1.5 pvu. Also, at the 700 mb level in Fig. 8, the contours of 1 and 1.5 pvu are evidently connected with those at 500 mb.

So, analysis of the cross-sections leads us to the following results:

In both cases, two baroclinic zones are revealed associated with two cold surges; the tropopause folds correspond to their baroclinic zones. Between the two surges, warmer air can be observed which manifests itself as a trough of isentropes. This feature is well-defined on 12 November and but slightly marked in the middle troposphere on 16 November.

On 12 November, a deep local tropopause funnel, developed in the rear of the wave on the streamer, passes over the station, bringing the stratospherically influenced air. In the afternoon of 12 November and during the next night, a tongue of this air drags behind the tropopause funnel, as viewed from above both at WV and PV images.

On 16 November, the tongue of stratospherically influenced air, which could cause increased ozone, is apparently connected not with the first cold surge, but with the second one. The lower part of the tongue seems to be displaced to southwest with respect to the tropopause funnel (as viewed from above) for a distance about 250 km.

8. Trajectories

The isentropic trajectories produced (on the basis of reanalysis) by NOAA Air Research Laboratory are used to estimate the air particle motion. The backward 5-day trajectories ending at different levels above the station and in its vicinity (not shown) indicate that the air, which occupied the area on 12 and 16 November at 12:00 UTC and the next 12 h, was descending from upper-tropospheric and substratospheric levels to the middle troposphere, down to the level of the station.

In Fig. 9, the trajectories ending at 12:00 UTC in 4 points surrounding the station at 200 m a.s.l., are shown. Elevations of the points vary from 370 to 3700 m a.s.l.; the point of 43° N, 42° E elevation is close to that of the station.

Interactive Discussion

It is interesting to note that the trajectories for 12 November exhibit very fast sinking on 9 November (from 8–10 to 3–5 km), but slow descent during last 24 h. That is, the particles descended over the Atlantic in the layer with strong winds (jet stream). On 8 November, 00:00 UTC, all 4 particles are found at the west coast of the streamer over the Atlantic (not shown). During next 12 h, the trajectories converge, and the particles descend along the slope of the streamer (to the south of the Ireland). Later, they sink to the bottom of the funnel (which develops on the streamer) and move, with the latter, horizontally over Europe approaching from northwest the area under study. On 16 November, on the contrary, the descent was fast during last three days, from 6–8 km levels. The start points, 5 days ago, are at 8–10 km levels. The trajectory 1 (Fig. 9, right) with the ending point slightly to the north, comes from the Atlantic, while three other trajectories come from Europe and then the Mediterranean. All they travel in the areas of high tropopause and then descend and join each other in the main streamer.

9. Discussion

Aiming to reveal causes of ozone concentration changes on 12–13 and 16–17 November 2001, we study atmospheric processes in these two cases which have much in common, though significant differences also exist.

Sharp drops in ozone concentration (to 7–8 ppb) associated with cold front passages in the night of 11–12 November and in the morning of 16 November, accompanied by $RH=100\%$ and overcast weather, have succeeded by fast clearing up, ozone growth to 43–45 ppb and RH decrease. These features are observed in nighttime or early in the morning, so that photochemical generation of ozone could not contribute significantly. Ozone concentrations above 40 ppb are registered during 12 and 4 h on 12 and 16 November, respectively, and then decrease after warm front passage (12 November) or after RH increase in the tropospheric cold post-frontal airmass (16 November). Between the two periods of sharp changes, ozone concentration varies near the level of 30 ppb.

Interactive Discussion

The ozone peaks are not high, and the maximum values are not stratospheric. However, against the background of rather homogeneous ozone, with no diurnal cycle, the two similar “drop-and-peak” events associated with cold fronts can be considered to be signatures of the fronts in the ozonometric data. The cold fronts in both cases are characterized with narrow cloud zones and, evidently, with pronounced sinking motions in the immediate rear of the fronts. Analysis of synoptic-scale flows shows that deep descending motions associated with cold air outbreaks took place in both cases.

During the period from 11 to 17 November, over the European Region, a deep trough in the troposphere is observed as oriented from the Cola Peninsula to the south. By 16 November, the trough deepens and takes a shape of upside-down omega. Several cold surges, with their baroclinic frontal zones, originate in the west part of the trough. The cold surges are separated by volumes of air with lower baroclinicity. So, about 00:00 UTC of 12 November, a cold surge with its front passes over the ozonometric station near Kislovodsk; the cold airmass comes from the west. At the WV images, a band of dry air behind the cold front is oriented to north-east over the area under study. The front and the streamer are subject to baroclinic instability: two waves (or vortices) develop, with their centers (at 02:30 UTC) near Mineral Waters and Samara. In the surface pressure field, small, weak troughs correspond to the waves. Typical vertical circulation develops in the unstable waves: descending branches in their rear (cold) sectors can be considered as embryonic “dry air stream”, while in the warm sectors, embryonic “warm conveyor belts” cause moist advection and diffusion of the streamer. Well-defined zones of sinking in the cold sectors of the waves generate deep funnels of dynamic tropopause. One of the funnels is situated in the area under consideration. In the rear of the cold surge, a volume of warmer air moves from the west near the surface and in the free troposphere, followed by the second cold surge with the corresponding zone of descending air. This zone manifests itself at the WV images as an arch-shaped band from Stockholm to Riga – Moscow – Syktyvkar.

Time of the funnel passage over the station on 12 November (as it can be revealed both from WV images and PV field) is in a good agreement with beginning of ozone

Interactive Discussion

growth at the surface, in the dry and cold air. The cross-sections for 12:00 UTC reveal an isolated, deep funnel, rather typical in shape. Its motion in the middle troposphere is slower than above. As a result, a “tail” or tongue of stratospheric and stratospherically influenced air is formed upstream of the tropopause funnel as viewed from above.

5 This tail passes over the station during late afternoon of 12 November and next night, causing low *RH* and increased ozone. Horizontal size of the tongue in zonal direction (that is, approximately in the direction of airflow) is of order of 200 km. Note that the tropopause fold associated with the second cold surge this day also has its own tail stretched to the south of the fold viewed from above.

10 On 16 November, the situation has much in common. A sharply defined streamer, outlining the rear of the cold surge, is stretched from south-west to north-east over the area under study. The front is also unstable, with longer wavelength of the slowly growing disturbances. A segment of cold front which passes over the station is associated with the leading part of the wave (embryonic warm conveyor belt). As a result, the
15 streamer contours are diffuse in this area, the streamer itself less dark at WV images, and the tropopause fold not deep: its bottom is at about 6 km a.s.l., and no response to its passage can be revealed in the ozonometric data at the station.

To the north of this streamer, the second cold surge is well-defined with its tropopause fold, stretched, as a distinct arch, from the Gulf of Bothnia to Riga, Minsk,
20 and Moscow. The tongue of stratospherically influenced air, which could cause increased ozone, is apparently connected with this second cold surge. The lower part of the tongue is stretched for about 250 km as a quasi-horizontal layer of slightly increased PV in the middle troposphere.

25 The 5-day backward trajectories show that the air which seems to cause increased ozone was subject to intense sinking. So, the air particles, which reached the area under study on 12 November at 12:00 UTC, descended from 8–10 km agl to 3–5 km during 9 November over the Atlantic and later descended but slowly. That is, this air (stratospheric or stratospheric at the initial points of the trajectories) was transferred in the middle troposphere during last 2–3 days. This result can be considered as an

illustration of a comment in (Stohl et al., 2000) about “indirectly intruding stratospheric air” which travels horizontally over some period and thus loses, to some extent, its stratospheric properties.

On 16 November the air also descended from the upper troposphere and lower stratosphere; the fastest sinking occurs during last 3 days. In both cases, evidently, the air causing increased ozone in the rear of the cold fronts can be considered as “aged” stratospheric intrusions.

10. Conclusions

The following conclusions can be drawn from the analysis of two cases of sharp changes in ozone concentration at the mountain station near Kislovodsk.

At the station, situated at 2070 m a.s.l., rather typical narrow cold fronts with fast clearing-up in the rear of cloud zone, are associated with a characteristic “drop-and-peak” signature in the ozonometric data, along with high (100%) and low (about 50%) *RH*. Neither diurnal cycle nor photochemical generation could produce these specific changes in ozone and *RH*. They are evidently caused by descending motions transporting substratospheric or stratospherically influenced air from the areas of tropopause folding.

The tropopause folds, developing at the cyclonic sides of tropospheric jet streams, in the baroclinic zones of cold air deep outbreaks, in the cases under study are not too deep: the surface of $PV=1$ pvu, that is, the lower dynamic tropopause, does not reach 850 mb level. However, the cross-sections of PV field (apparently too smoothed due to scarcity of data) show that the stratospherically influenced or substratospheric air could reach the area of the station at the time corresponding to the ozone peaks. This air came to the station within the “tongues” or “tails” stretched from the tropopause folds as viewed from above both at WV images and at dynamic tropopause maps. These tongues intrude tropospheric levels and flow under the overlying upper-tropospheric air. Apparently, they can flow far from their tropopause folds (viewed from above) – for

Interactive Discussion

distances about 250 km. These volumes of air with slightly increased ozone and PV and with low RH seem to represent “aged” stratospheric intrusions. This air traveled in the troposphere during last 2–3 days, after descending from the levels of 8–10 km.

5 The shape of the streamers outlining the cold outbreaks and lying behind their fronts is highly sensitive to hydrodynamic instability of the baroclinic frontal zones. In both cases, wave disturbances are clearly seen at the WV images and at the dynamic tropopause maps. In the rear sector of the wave, a deep tropopause funnel can develop (the case of 12 November) as a result of strong sinking. This effect can be interpreted as that of incipient dry air stream. In the leading part of the wave, a counterpart effect
10 of incipient warm conveyor belt leads to slowing down of the tropopause folding and to diffusion of the streamer. As a result, the fold here does not penetrate the middle troposphere (the case of 16 November). The process of origination and growth of the unstable waves is almost undistinguishable in the pressure field and, at the same time, exceptionally well-defined at the WV images and dynamic tropopause maps. This feature
15 represents a further confirmation of the conclusion by Hoskins (1991) and Hoskins et al. (1985) about high potential of PV-analysis of real weather systems.
